| 20. ABSTRACT (Continue on reverse side if necessary and identify by block number)<br>This investigation utilized historical and recent aerial photographs and satellite imagery in 1) estimating changes in positions of the high-water line and sea cliff break and base, in rates of accretion and/or erosion, and in volumes of transported sediment, and 2) providing a preliminary evaluation of the direction of littoral transport along the outer Cape Cod coast. Using aerial photographs acquired in 1938, 1952, 1971 and 1974 with manual photointerpretation techniques, changes in the distances from selected reference points to the cliff break, cliff base and the high-water line were measured. LANDSAT-1 and -2 imagery acquired from 1 September 1972 to 28 May 1975 was evaluated for use in determining the directions of littoral transport that are active the predominant amount of time.<br><i>CONT'D</i> |                       |  |

## 20. Abstract (cont'd).

Although the imagery has been very useful for this purpose at other locations, it proved to be useless along the outer shore of Cape Cod. Largest net migrations of the high water line from 1938 to 1974 occurred in the northern and southern portions of this coast. The northern maximum high water line was 321.4 ft, the southern was 1794.6 ft. The central portion of the coast was generally more stable with changes varying from 6.8 to 157.6 ft. Cliff-base recession rates varied from 0.4 to 7.3 ft/yr. Maximum estimated net volume of sediment deposited per linear foot of beach from 1938 to 1974 was 334 yd<sup>3</sup> (based on 2 yd<sup>3</sup>/ft of recession or accretion); maximum eroded was 914 yd<sup>3</sup>. Changes in the configuration of spits were used to evaluate directions of littoral transport since suspended-sediment concentrations were generally not sufficient to act as natural tracers of surface currents. Based on the literature and a determination of the portion of the coast perpendicular to the direction of dominant wave approach, the location of the nodal zone for predominant littoral directions of drift probably shifts between the area near Spectacle Pond and North Truro Air Force Station. This investigation has illustrated a photo interpretation technique that is useful in performing a reconnaissance of coastal change. The data obtained from this method can be used to supplement those acquired by ground surveys and are valid as first approximations for planning subsequent, more detailed surveys.

## PREFACE

This report was prepared by Lawrence W. Gatto, Research Geologist, of the Earth Sciences Branch, Research Division, U.S. Army Cold Regions Research and Engineering Laboratory. The work was funded by the U.S. Army Engineer Division, New England (NED), under Intra-Army Order 75-C-08.

The author expresses appreciation to Allan Hartwell (Normandeau Associates, Inc., Bedford, New Hampshire) and Dr. Victor Goldsmith (Virginia Institute of Marine Science, Gloucester Point, Virginia) for technical review of the manuscript; Dr. Harlan L. McKim (CRREL) for a review of the project proposal and support throughout the project; Cecil Wentworth (NED) for assistance in definition of project objective; Carolyn Merry (CRREL), Dr. Joseph Horowitz (NED) and Thomas Marlar (CRREL) for assistance in acquisition of aerial photographs and satellite imagery; Robert Demars (CRREL) for photographic processing; Michael Hutton (CRREL), Richard Haugen (CRREL), Thomas Marlar, and Allen DeWall (U.S. Army Coastal Engineering Research Center) for critical suggestions; Thomas Bruha (NED) and Dr. Duwayne Anderson (CRREL) for encouragement and support; and especially, Eleanor Huke (CRREL) for assistance in coastline change measurements, data reduction, calculations of erosion/deposition rates and preparation of illustrations.

The contents of this report are not to be used for advertising or promotional purposes. Citation of brand names does not constitute an official endorsement or approval of the use of such commercial products.

# SHORELINE CHANGES ALONG THE OUTER SHORE OF CAPE COD FROM LONG POINT TO MONOMOY POINT

Lawrence W. Gatto

## INTRODUCTION

The protection and preservation of coastal areas and shorelines have become increasingly important with more intensive use and development of these areas by the growing population. Governmental concerns for the coastal zone are well illustrated by legislation enacted to protect, and by investigations initiated to understand, the processes that affect this environment. Special value has been assigned to the coast of Cape Cod from Long Point to Monomoy Point (Fig. 1) because of its historical and recreational importance. A major portion of this shoreline was designated the Cape Cod National Seashore in 1961.

The process of most concern along the outer Cape Cod shoreline is erosion of the dunes, bluffs (composed of unconsolidated glacial material), and beaches. From late fall through spring, northeasterly and easterly storms build up tidal surges that occasionally approach hurricane levels. Because of the open ocean exposure, storms with these high tidal surges (7.8 to 10.6 ft above mean low water) frequently allow large storm-driven waves to overtop the beaches and attack the base of the cliffs and dunes. Erosion along the shoreline is estimated to average in excess of 3 ft/yr, and during some years certain sections have eroded in excess of 8 ft/yr. The erosion has progressed to the point where certain natural features and shoreline facilities are threatened. This has been particularly serious at some National Park Service parking areas that are located near eroding cliffs (U.S. Army Engineer Division, New England 1975).

A beach erosion control study of the entire shoreline was authorized by Congress in a resolution adopted 2 December 1970 to make a "... survey of the easterly shores of the outer arm of Cape Cod, Massachusetts, extending from Provincetown to the southern extremity of Nauset Beach in the interest of beach erosion control, hurricane protection and allied pur-

poses." It was recognized that the erosion processes and problems along this shoreline are very complex. The study would require a detailed analysis of storm flood tide level frequencies, wave climate (including wave energy and alongshore littoral transport), shoreline changes

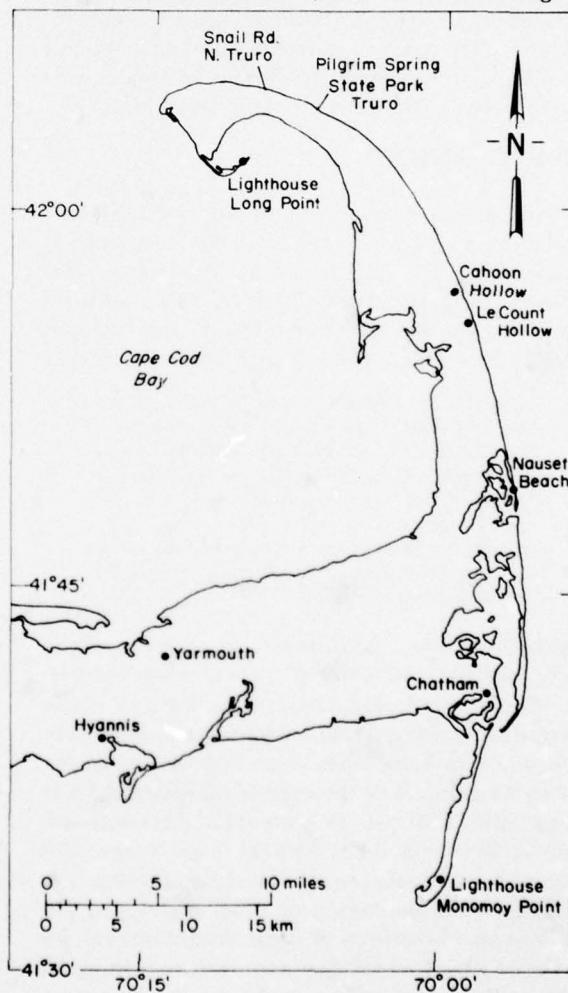

Figure 1. Study area from Long Point to Monomoy Point along the outer Cape Cod coast.

and engineering and economic studies on possible alternative beach erosion control measures. Consideration would need to include beach widening and dune restoration and construction of groin structures, rock revetments, seawalls and other shoreline control devices designed to provide a stable shoreline.

As an initial step in addressing this erosion problem, this investigation was designed primarily to determine past patterns of shoreline change, and to estimate changes in positions of the high water line and cliff break (i.e. the top) and base as well as rates of net accretion and/or erosion utilizing data obtained from historical and recent aerial photographs along the outer shore of Cape Cod. Secondary objectives were to estimate volumes of material eroded from or accreted along the shoreline and to provide a preliminary evaluation of directions of littoral transport utilizing LANDSAT-1 and -2 imagery. These data would be useful in evaluating and planning future measures that could reduce or eliminate coastal erosion along this shore.

## BACKGROUND

The utility of aerial photographs and satellite imagery in coastal studies is well established (Huebner 1975, Freden et al. 1973 and 1974, NASA 1974 and 1975, Stafford 1971, Stafford and Langfelder 1971, and Dolan and Vincent 1973). Dolan and Vincent (1973) concluded that

a significant amount of information concerning the state of the coastal environment can be obtained from high-altitude aerial photographs. By comparing photographic sequences, averaged conditions as well as rates of changes can be established. In addition, regional relationships provide an integration of the processes and sand responses occurring along the coast.

However, the limitations inherent in the photographs and imagery\* should be considered prior to quantification of coastal changes. These disadvantages or limitations are 1) shorelines are shown at specific times when coastal conditions may be atypical of the normal equilibrium state (e.g. after storms), 2) horizontal distances are easily determined but vertical relief is more difficult to calculate, and 3) the scale of imagery is variable and geometric or relief distortions are common. The effects of these limitations can be reduced by 1) repetitive acquisition of imagery during typical weather conditions, 2) utilization of empirical formulas not requiring vertical

\* In this report photographs and other types of imagery are collectively referred to as imagery.

relief data to estimate volumes of eroded or accreted sediments, and 3) utilization of geometrically corrected and rectified imagery to greatly reduce the measurement errors that result from distortions. Since scale variations and geometric distortions tend to increase from the central to the peripheral portions of an image, measurements can be made in the middle portion of the image where distortions are minimal if corrected images are not available. Komar (1976) reports that sea cliff retreat rates are commonly determined by comparing a series of aerial photographs or by repeated ground surveys.

In spite of these limitations there are several advantages in using imagery: 1) a permanent record of beach conditions existing at the time of image acquisition is obtained, 2) more detail is available than on maps or charts, 3) the processes active during varying tidal and seasonal conditions can be observed, and 4) data can be more economically acquired from imagery than from extensive field surveys. However, data collected from imagery may not be as accurate as that acquired from field reconnaissance; therefore, the requirements and objectives of an investigation must be considered in determining the application of remote sensing or photo interpretation techniques. Since this project was designed as a preliminary reconnaissance of relative changes along extended stretches of the coast and was not intended to determine absolute values of erosion or accretion, imagery was a convenient and useful tool in accomplishing the project's objectives.

## PREVIOUS INVESTIGATIONS

The geologic history of Cape Cod has been discussed by several investigators (Zeigler et al. 1964a, Fisher 1972, Chute 1939, Oldale et al. 1973, and Ballard and Uchupi 1974). Bedrock, surficial geology, and sedimentary characteristics were presented in a series of U.S. Geological Survey maps (Koteff et al. 1967, Oldale 1968, Oldale et al. 1971, Oldale and Koteff 1970, Koteff et al. 1968, Tucholke et al. 1972, and Schlee et al. 1973). DeWall et al. (1977) gave the following general physical factors that characterize the beach along the Atlantic Ocean side of Cape Cod:

tidal range, 7.6 ft; littoral material, medium to coarse with quartz (80-92%), rock fragments and garnet; narrow beach in front of clifted shoreline of glacial sand, gravel, and cobbles, no houses on beach.

Shepard and Wanless (1971) described the condition of the coast, provided estimates of cliff recession at several locations, and quantitatively described these changes based on past records and aerial photographs. They also discussed the general offshore conditions that exist along the outer shore of the Cape. Tidal currents are strong, the shelf slopes uniformly to a depth of 500 ft, and although there are numerous offshore bars 20-30 ft below mean low water, a wave-cut bench has not formed offshore from Cape Cod due to erodability of the glacial material.

Various determinations of rates of coastline change have been made from historic records (i.e. maps and descriptions) and field data. Johnson (1925) reported 3 miles of total recession in the narrow neck near Cape Cod Light.\* Zeigler et al. (1964b) compared the existing cliffted portion of the shoreline with that surveyed in 1887 and found an average retreat of 2.5 ft/yr or 175 ft from 1887 to 1957. They also reported erosion rates of 1-4 ft/yr at other locations along the cliffted coast, and 3.0-5.5 ft/yr just north of Nauset Inlet. They calculated accretion rates of 0.5-5.0 ft/yr from 1887 to 1957 along the north coast of the Cape Race-Provincetown area. Marindin (1889) and Davis (1896) also reported that erosion rates of the cliffs between Nauset and Highland differ, being greatest in the central portion of this coast.

Arpin (1970) reported that portions of the southeasterly side of the outer arm of Cape Cod were eroding as much as 15 ft/yr. Goldsmith (1972) calculated that as much as 151 ft of erosion had occurred at a specific site on the northeast side of Monomoy Island near Shooter's Island between June 1968 and March 1970 (for an average rate of 82.5 ft/yr), though erosion rates were considerably lower to the north and south. Successive shoreline changes between 1887, 1940, 1953, and 1964 in the Monomoy Point area were shown on USGS map GQ-787 (Koteff et al. 1968). Changes between 1887, 1940, 1947, and 1969 in the Chatham area and along the Nauset Beach Spit were shown in USGS map GQ-911 (Oldale and Koteff 1970). Hayes et al. (1973) discussed changes that have occurred on Nauset Spit from 1872, 1887, 1902, and 1965, bar morphology along several sections of the Cape Cod coast, and the nearshore bar and rip-current system evident near Truro. Bruha† reported that summer waves are commonly 3 to 4 ft high, and

the beach width along the cliffted portion of the coast is typically 100 ft. During the winter the beach at the cliff base is virtually absent, with wave breaking at the base and storm waves producing spray 10 ft to 15 ft high.

Extremely rapid changes in coastline configuration and nearshore bathymetry on Cape Cod have been caused by storms (Zeigler et al. 1959). Maximum waves on the outer beaches are caused by storms that pass east of the Cape, producing onshore winds that progressively shift from the east, northeast, north, and finally northwest. Storms that pass west and northwest of outer Cape Cod produce southeast, south, southwest, and west winds which cause smaller, less-developed waves (Zeigler et al. 1959).

The cliff toe at Highland retreated approximately 4 ft and the top of the cliff 4.5 ft in 4.25 years from October 1953 to January 1958 (Zeigler et al. 1959). The entire cliffted portion of the coast from Highland to Nauset was differentially eroded during the April 1958 storm: erosion amounted to 30-50 ft at the Nauset parking lot, 12.5 ft in the central part of the outer Cape and 4 ft from the Highland area. An estimated 150,000 yd<sup>3</sup> of material was eroded from the coastline during the storm. Recovery to prestorm conditions appeared to occur within a few days (Zeigler et al. 1959).

DeWall et al. (1977) reported the changes in beach profiles due to a storm on 17 December 1970 at 10 locations from the north end of Newcomb Hollow beach (opposite Horseleach Pond) to the central portion of the northern spit at the mouth of Nauset Harbor. They noted a trend of decreasing erosion from the high cliffs at Wellfleet to the low accreting spit at Nauset Beach. Generally, erosion appeared greatest in the profile above +2 ft mean sea level (MSL), and deposition primarily occurred below +1 ft MSL. Average net unit volume change above MSL was reported as -5.5 yd<sup>3</sup>/ft.

The nearshore bathymetry and location of offshore bars along the Cape Cod coast significantly influence the amount of beach erosion at specific locations (Zeigler et al. 1959). Erosion may be reduced where the shelf shoals or where offshore bars occur because wave energy is dissipated prior to reaching the beach. Offshore bars may also increase shoreline erosion by causing wave refraction around the ends of the bars, since the refracted waves can be focused onto the shoreline opposite the ends of the bars.

\* Locations are shown on USGS maps in Appendix A.

† T. Bruha, Chief, Beach Erosion Section, U.S. Army Engineer Division, New England, personal communication, 1977.

The locations of these bars and shoals, which either protect the beach from or focus wave energy on the beach, are continually changing. This shifts the locations where maximum erosion occurs and causes great variability in erosion rates along the coast (Goldsmith and Colonel 1970). Zeigler et al. (1959) report that shore erosion is greater behind openings in offshore bars, and migration of these openings shifts the locus of maximum cut and fill laterally along the beach. Komar (1976) reports that the positions of rips and the overall nearshore circulation cell configuration are governed by wave refraction and hence by offshore topography.

### ANALYTICAL PROCEDURES

The approach of this project was that of an office study (U.S. Army CERC 1975) utilizing available data in several forms to provide information for subsequent and more detailed engineering studies. A chronological listing of the procedures followed during the project is presented in Table I. The availability of aerial photographs was determined for several sources. However, aerial photographs of the entire outer coast of Cape Cod could be obtained for only 1938, 1952, and 1971 (Table II) because

it was necessary to have historical photographs that had been acquired with the least possible time lag between flight lines. This was an attempt to provide as near a synoptic view of the coast as possible during each airphoto mission. Shoreline changes that occurred between the times the photographs were taken were minimized. Recent coastal conditions were recorded during a single aerial photographic mission on 11 October 1974. Shoreline changes for 1938, 1952, 1971, and 1974 were mapped on USGS topographic maps as shown in Appendix A, Figures A1-A6. The reference points used for photographic interpretation are indicated on these maps.

DeWall\* suggested that tropical storm and hurricane data should be checked to see if any of the aerial photographs were acquired after major storms. If any had been, atypical post-storm conditions would exist and the measurements would not be representative of the reestablished, prestorm conditions of that particular time. Tropical storms and hurricanes that passed through or near Cape Cod at times close to the photo acquisition dates are shown in Table III. Zeigler et al. (1959) report that beach erosion along Cape Cod occurs very rapidly during storms and that recovery to prestorm conditions occurs within a few days. Since none of the

storms in Table III occurred immediately before the aerial photographs were taken, it is likely that the coastal conditions were typical.

Harris (1975) reports that the heaviest concentration of hurricanes in New England occurred in the 1950's; no significant hurricane had reached the New England coast since Hurricane Donna (12 September 1960) which moved inland from Long Island to Maine. Note the large mean change in the high water line for the 1952-1971 interval (App. BIII). Normal expectancy of hurricane occurrence in New England is from 5 to 10 per 100 years. Additional hurricanes from 1938 to 1974 occurred on: 14 September 1944 and 31 August 1954 (both moving through Rhode Island), on 11 September 1954 (felt mostly in Cape Cod), on 15-17 October 1955 (moving southeast of Cape Cod), and on 21 September 1961 (moving south of Cape Cod and not significantly affecting the shoreline).

Zeigler et al. (1959) provided a detailed discussion of storms affecting Cape Cod and the resulting amounts of erosion or accretion along the beach. Goldsmith (1972) also summarized previous storm frequency data of Mather (1965) which showed two periods of increased frequency of damaging coastal storms on the U.S. east coast from 1921 to 1964. One period peaked in 1933 when seven major storms were reported and the other in 1958 when 13 major storms occurred. In regard to periods preceding the 1938 and 1952 imagery, Mather's (1965) data showed two storms in 1937, one in 1938, six in 1951, and five in 1952. Mather's data also indicated that, no matter what the storm frequency for a given period, certain Atlantic coast areas will always be the most likely to suffer extensive damage. Cape Cod is such an area.

Knowledge of the tidal stage during these photographic missions was required to measure

the position of the high-water line (Table IV). Most of these stages were available from tables of predicted tides; however, the 1938 tides were calculated by the National Ocean Survey, Rockville, Maryland, since tide tables for this time were not available. Predicted tides were used in all cases because no tide gauges are located on the outer Cape Cod coasts, and the heights and times of the predicted and actual tides along the site are reported to be comparable.\* Stormy weather conditions would reduce the reliability of the predicted tides; however, the weather was probably not stormy on the days the aerial photographs were acquired, and the predicted tides were likely to be very near the actual tides.

The tide was at or near high water when the photographs were acquired on 21 November 1938 and at or near low water when the two photographs were taken on 14 December 1938. Consequently, the water's edge approximated the high-water line on the 21 November 1938 photographs and measurements were made from inland reference points to the water line. On the 14 December 1938 photographs, measurements from points 18, 20, 88, and 89 were made to the high-water line marked by a debris line or tonal change in the beach sediment.

*Tidal stages during acquisition of the 1952 photographs were as follows: ebb tide on 3 June, low tide on 13 July, and high tide on 25 July. The water's edge approximated the high-water line on photographs acquired on 25 July showing points 1-34, 58-65, and 92-97; measurements were made to the water's edge. Measurements were made to the high-water line on the beach for the 13 July photographs showing points 35-51. Measurements were made to the water's edge on 3 June photographs with points 67-89. A distinct high-water line was not apparent on the narrow beach near points 67-89; consequently, the difference between the high-water line and water's edge was probably minimal. The 1971 photographs were taken during or near high tide and measurements were made to the water's edge for all the points. The 1974 photographs were taken during ebb tide and measurements were made to the high-water line.*

Working photomosaics were prepared for each of the four years, and a total of 97 man-made and natural features, observable on all four sets of photographs, were originally selected as possible inland reference points for measuring distances to the high-water line, cliff

break, and cliff base. However, the natural features (small ponds and clumps of vegetation) were generally avoided in the final selection of the 47 reference points because their shapes and positions were not always stable from year to year. Only one natural feature, a small pond (point 76, Fig. A4) near Nauset inlet, was used because there were no man-made features in that immediate area. The pond was located on a marshy island inland from the changing beach,

\* T. Bruha, personal communication, 1977.

and its position was determined by inspection of the four sets of photographs to be stable.

Stable man-made features (e.g. buildings, road intersections, irrigation ditches, and bridges) were chosen for 46 of the reference points. Twenty-six of the man-made points (numbered between 1-44) were located along the coast from Long Point Lighthouse to north of Cahoon Hollow (Fig. 1, A1, A2 and A3). Twelve (49-81) were located from near Cahoon Hollow to the northern portion of Nauset Beach (Fig. 1, A3 and A4). The remaining eight (88-97) were located from the southern portion of Nauset Beach to Monomoy Point Lighthouse (Fig. 1, A5 and A6). Photographs that showed the reference points in the central portion of the print, where geometric distortion was minimal, were used. For example, Figure 2 was used to measure distances from point 37 but distances from point 36 were measured on the adjacent photograph.

At low tide the high-water line is usually visible as a line of debris on, or tonal change (b, Fig. 2) in, the beach sands (d, Fig. 2). Sand upslope (landward) of the high-water line is generally lighter than the more moist sand that is inundated during periods of high tide, and the water's edge approximates this high-water line on photographs acquired during high tide. The cliff break (a, Fig. 2) is defined by a distinct line between dark vegetation on the southwest side and the lighter (streaked) glacial material on the cliff face (between a and c, the toe or base of the cliff) on the northeast side. The cliffted portion of the coast extends from the southern end of Head of the Meadow Beach (point 31, Fig. A2) to south of Nauset Beach Lighthouse (point 69, Fig. A4).

Beach points were marked along a line, or ray, drawn approximately perpendicularly to the coast from the reference points (point 37, Fig. 2). This reference line was drawn at an angle which varied at different reference points but was held constant for a particular point. For example, in Figure 2 the reference line drawn approximately perpendicularly to the coast from point 37 is at an angle of 87° from the baseline between points 36 and 37. The 87° angle was also used at point 37 on the 1938, 1952, 1971, and 1974 photographs to reduce the possibility of error caused by moving the reference of measurement. A Vernac Direct-Reading Optical Measuring Instrument, accurate to the nearest 0.0001 in., was mounted on a Richards light table and was used to make the measurements on the photographs. The prints were placed on the light table and measurements were made between

the middle of the pin holes marking the reference points and beach features.

The scale of each print was variable due to changes in terrain elevation, aircraft altitude, camera tilt, etc. Therefore, scales were determined several times on each print and averaged in the area nearest the reference and beach points. Ground distances were calculated by multiplying the Vernac readings by the average scale. Distances to the beach points for each year were recorded and annual rates of coastal erosion or accretion were determined.

Volumes of eroded or accreted sediment were estimated using a revised version of the following empirical relationship (Corps of Engineers 1964, U.S. Army CERC 1975):

$$1 \text{ ft of beach erosion perpendicular to the beach} = 1 \text{ yd}^3 \text{ of material/linear ft of beach.}$$

Modifications of this empirical relationship have been used successfully at Yaupon Beach, Long Beach, and Morehead City Harbor, North Carolina (U.S. Army Corps of Engineers, Wilmington District 1973 and 1976). These modifications were used to convert shoreline movements to volume changes. It was assumed when making the conversions that the entire active shoreline profile moved at the same rate as the shoreline; i.e. an equilibrium profile existed that changed only in position during the time between surveys. At Yaupon Beach and Long Beach the conversion factor was 1.54  $\text{yd}^3/\text{linear ft of beach}$  (using the average profile configuration), and at Morehead City Harbor it was 1.30  $\text{yd}^3/\text{linear ft}$ , providing volume estimates that compared favorably to measured values of volumetric change at the respective locations. Extensive field profile measurements showed reasonably good correlation between the values from this "rule of thumb" relationship and the field values and also indicated that the beach sediment was transported longshore and offshore within the zone from 7 to 8 ft above mean sea level to 20 ft below.\* Vallianos and Jarrett indicated that these values of transported material are valid as estimates of long-term trends over 10 to 20 years for beach/nearshore sediment, not for sediment resulting directly from cliff erosion.

Goldsmit† reported that "converting horizontal shoreline changes from aerial

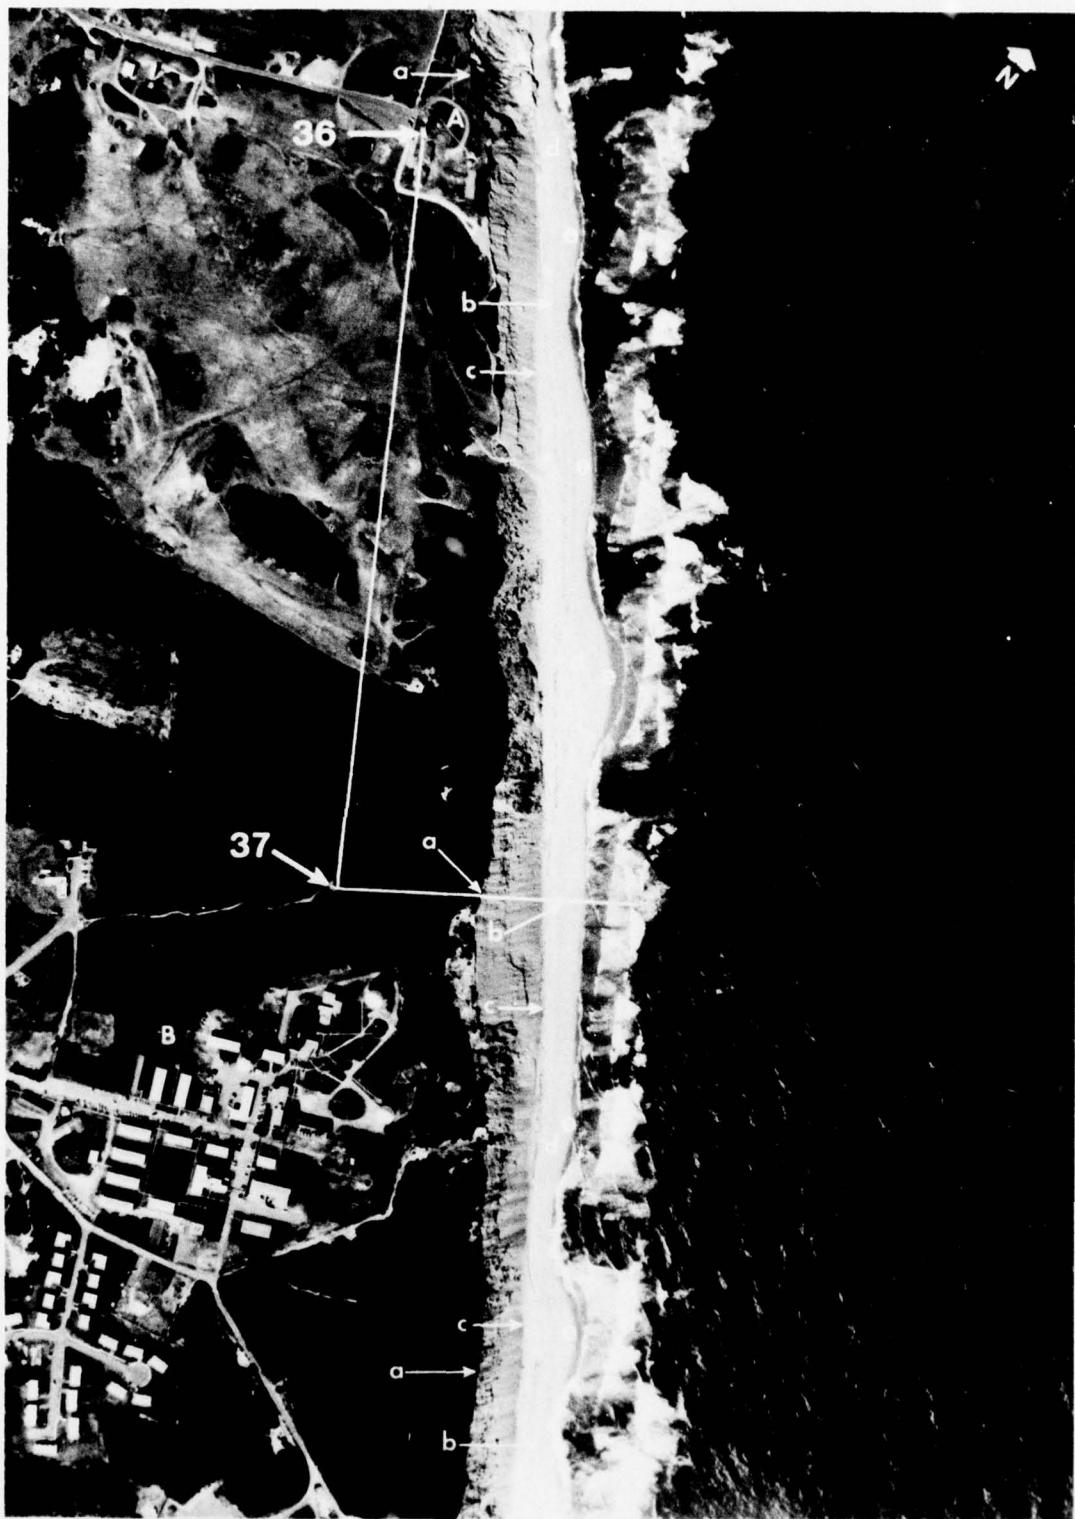

Figure 2. The Highland area on the eastern Cape Cod coast from Highland Light Coast Guard Station (A) to North Truro Air Force Station (B). Aerial photograph acquired 11 October 1974; approximate scale, 1:6700. (a, cliff break; b, tonal change in sand, marking landward extreme of previous high water; c, base of cliff; d, beach sand; e, sand waves making up sand wave field).

photographs is tricky at best." He suggested that the conversion coefficient be varied between the cliffed portion and the low-duned portions on the flanks of the shoreline. Goldsmith et al. (1972) also report that the use of the empirical formula is inappropriate for indicating trends of beach volume changes associated with strandline migration on Monomoy-Nauset beaches of Cape Cod. For this area, they showed that the most active parts of the beach (in terms of sand transport) are the low tide, near high-tide, and spring high-tide zones — the center of the beach face is relatively inactive. Traditional measurements of beach width are not necessarily reliable indications of sand volume changes on beaches. In addition, they reported that very active profiles can occur with little or no net sand erosion or accretion to the total profile.

DeWall et al. (1977) reported that only 73% of the beach profiles along the U.S. Atlantic coast showed an increase in volume when shorelines accreted or a volumetric decrease when shorelines retreated. Everts' (1973) data also showed that a prograding (accreting) beach may lose volume. Komar (1976) reports that, when beach profiles change from the swell to storm and back, the volume of sand moved laterally from a particular beach location remains relatively constant.

Personnel at the U.S. Army Coastal Engineering Research Center\* reported that the 1:1 relationship between changes in beach width and volumes of material eroded is recommended only where annual physical environmental conditions are similar to those at the area where the relationship was proven applicable. They suggested that, for an area of generally greater tidal range and heavy wave action, the coefficient for this empirical rule could approach 1.5 to even 2. Bruha and Wentworth suggested using a conversion factor of 2 yr<sup>1</sup>/linear ft for Cape Cod because the tidal range along the shoreline is high ( $\cong 7.6$  ft), the coast experiences heavy wave action and strong tidal currents, and the glacial material in the bluffs erodes rapidly along the shore. This 1:2 relationship was used for calculations given in this report; therefore the volume data presented are estimates only, and are considered only as supportive data for actual ground measurements. They were compared to reported field survey data and can be compared to future survey data to evaluate the utility of the empirical formula in locations north of the Monomoy-Nauset area.

\*As reported by Bruha, personal communication, 1977.

† Bruha and Wentworth, personal communication, 1974 and 1977

The direction of sediment transport along Cape Cod was evaluated by use of LANDSAT-1 and -2 multispectral scanner (MSS) imagery acquired from 1 September 1972 to 28 May 1975. Suspended sediment patterns in the littoral zone typically observed on the LANDSAT bands 4 (0.5-0.6  $\mu\text{m}$ ) and 5 (0.6-0.7  $\mu\text{m}$ ) imagery were not apparent on this LANDSAT imagery. As a result, the orientation of spits was used to infer dominant directions of littoral transport. Generally, band 6 (0.7-0.8  $\mu\text{m}$ ) and 7 (0.8-1.1  $\mu\text{m}$ ) imagery show the distinction between land and water most prominently.

Special interpretive techniques (i.e. computer processing, densitometry, etc.) were not required in this investigation. Standard photointerpretation methods were sufficient to provide data on coastal changes. However, several LANDSAT images were photographically enhanced to improve contrast and clarity.

## RESULTS AND DISCUSSION

### Shoreline changes: High-water line

The distances in Table V were used to plot the high water line on U.S. Geological Survey 7.5-minute topographic maps (Fig. 3, A1-A6). The locations of the high-water line between reference points and at entrances to inlets or bays were not measured. They were drawn from photographs reduced to the scale of the base maps (1:24000) to produce overlays which showed the entire shoreline. The distances in Table V were also used to calculate the total amount of change in the position of the high-water line and the annual rates of change for each period from 1938 to 1952, 1952 to 1971, and 1971 to 1974 (Table VI, Fig. 4). In Table VI, the plus (+) sign indicates accretion (deposition) or movement of the high-water line seaward from its position observed on the previous year's photographs. The minus (-) sign indicates erosion or a landward shift of the high-water line. Table VII shows the total changes and mean annual rates of change for the composite interval, 1938 to 1974. Figures 5 and 6 are graphic displays of the data from Table VII.

Positions of the high-water line in Figures A1-A6 are the locations as photographed in 1938, 1952, 1971, and 1974. The accretional or erosional trends indicated by these relative positions do not reflect short-term changes that occurred between the periods when the photographs were taken, but they approximate longer term trends or net changes that result from many

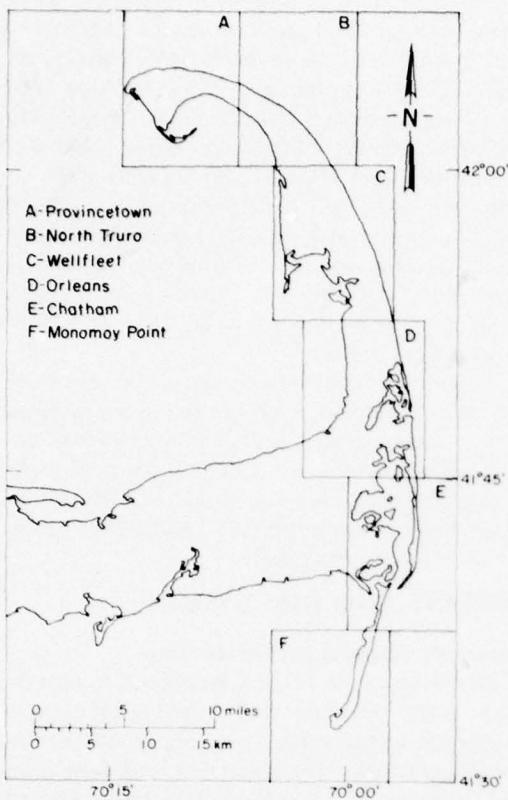

Figure 3. Locations of U.S. Geological Survey topographic maps used as base maps for plates A-F (Fig. A1-A6).

ephemeral events. Several local uniform patterns are recognizable, although variability is generally high along most of the outer Cape Cod coast.

The tip of Long Point and the entrance to Hatches Harbor have shifted frequently since 1938, while minor net changes occurred from Wood End to the northwest side of Provincetown Beach (Fig. 5). The total amount of change (Fig. 6) at point 6 was 55.7 ft, and as much as 414.7 ft of change occurred at point 13. Along the coast from Race Point to Pilgrim Spring State Park, the net change in position of the high-water line from 1938 to 1974 was greatest between points 13 and 18 (Fig. A1). The water line shifted approximately 321, 223, and 102 ft in a net seaward direction from 1938 to 1974 at points 13, 14, and 18, respectively (Table VII). The total amount of change during the investigation period was greater than 164 ft for all the points east and southeast of point 9 (Table VII) shown in Figure A1. Measurements made on the photographs indicated that this was the most mobile portion of the coast shown in Figure A1.

The position of the high-water line northeast of Salt Meadow (Fig. A2) and southeast of Longnook Beach shifted seaward and landward regularly. It was reasonably stable at the North Truro Air Force Station (point 37), but it receded regularly between Salt Meadow (point 31) and the Air Force Station (point 37). This portion of the shore where erosion is predominant may approximate the location of the nodal point of coastal transport.

Except for points 37, 41 and 42, the total amount of change from 1938 to 1974 was greater than 178 ft (point 35) for the points in Figure A2. This section of coast was generally as mobile as the southeastern portion on Figure A1. Net annual rates of change (Table VII) varied from 0.3 to 8.8 ft/yr at different locations over the 35.9-year period. Generally higher net rates occurred in the northeastern portion (points 24-36) of this part of the coast.

The coast shown in Figure A3 shifted less than that on Figure A2. Variability in the total amount of change was also less. Variability at the points in Figure A2 was from 34.2 ft at point 41 to 411.8 ft at point 36; in Figure A3 it was from 94.7 ft at point 50 to 389.0 ft at point 65. Net annual rates are generally low along this portion of the coast.

The coast between points 67 and 81 (Fig. A4) was generally more mobile than the portion in Figure A3. Net annual rates of change varied from 2.1 ft/yr (point 69) to 41.0 ft/yr (point 76); the total amount of change varied from 150.5 to 1473.6 ft. The greatest changes along this coast occurred at points 74, 76, and 78 at the entrance to Nauset Harbor. These very large changes are clearly shown on the aerial photographs acquired on 21 November 1938, 3 June 1952, 7 August 1971, and 11 October 1974 (Fig. 7). This sequence shows net northerly growth of the spit on the south side of the harbor entrance. This spit apparently receded slightly southward some time around 1962 (see portion of the USGS 7.5-minute Orleans topographic quadrangle, 1962 revision in Fig. 7) but then grew northward again. The small spit on the north side in 1938 was eroded by 1952 and had moved very slightly south by 1962. It had continued to recede again by 1971, and by 1974 had receded northward, forming a new entrance. Shepard and Wanless (1971) describe changes at the harbor entrance from 1938-1962. Lynch-Blosse and Kumar (1976) discuss the relationship between direction of net longshore drift and shapes of tidal inlets, indicating that inlet shape forms in response to

Table V. Distances (ft) from reference points to the high water line, cliff break and cliff base measured on 1938, 1952, 1971, and 1974 aerial photographs.

| Reference points | Plate | Distance along shore* | 1938             |             |            | 1952              |             |            | 1971              |             |            | 1974               |             |            |

\* Distances were measured from intersection of the reference line and the shoreline to the next intersection point; starting at Point 1 to 97. Hoffritz opisometer (map meter) was used.

† Measurements made to water's edge except at points 18, 20, 88 and 89 where high-water line was used.

\*\* Measurements made to water's edge except at points 35-51 where high-water line was used; reference points 1 and 4 not shown on 1952 photographs.

†† Measurements made to water's edge since tides were at high water.

\*\*\* Measurements were made to high water line.

Table VI. Total changes (ft) and incremental mean annual rates of change (ft/yr) in positions of the high-water line.

| Reference points | 1938-1952    |  | 1952-1971    |  | 1971-1974    |   |
|------------------|--------------|--|--------------|--|--------------|---|

\*Difference between position in 1938 and 1974 (Table V).

†Net change  $\div$  35.9 years (Table VI, footnotes \*, †, \*\*).

\*\*Summation of total changes in Table VI whether accretion (+) or erosion (-); - in this column indicates total changes from Table V were always erosional.

sediment supply and longshore and tidal currents. Nauset Inlet fits their category of a straight inlet because its updrift and downdrift sides stretch along an average straight line forming the coastline. This type of inlet offers no clue

to the direction of longshore drift. Although Nauset Inlet (Fig. 7) changed its shape, it remained in the "straight" category from 1938 to 1974.

Only two stable reference points visible on the four sets of photographs for the area on Figure A5 were found. Consequently, except for the coast opposite points 88 and 89, positions of the high-water lines for the four years were drawn by tracing the water boundaries from the photographs after the photo scales were adjusted to the scale of the map. The measured net annual rates of change and total amount of change for points 88 and 89 were 16.7 and 19.5 ft/yr and 599.1 and 701.0 ft, respectively.

Deposition predominated at the tip of Nauset spit which migrated southward from 1938 to 1971. By 1974 this trend had stopped; the tip had been eroded and had migrated northwestwardly nearly 0.5 mile. Additional discussion of change in this area is available in Shepard and Wanless (1971), Koteff et al. (1968), and Oldale and Koteff (1970).

Monomoy Island was previously a spit attached to Morris Island as shown on 1938 and 1952 USGS maps. The 1961 edition of the Chatham 7.5-minute USGS topographic quadrangle showed that Monomoy and Morris Island were connected only by tidal flats. The separation, completed during the great Atlantic storm of March 1962, still existed in October 1974. From 1971 to 1974 the northern end of Monomoy Island and the tip of Nauset Beach spit migrated westward.

Extreme changes have occurred along Monomoy Island (Fig. A6). Net annual rates of change vary from 4.3 ft/yr at point 96 to 50.0 ft/yr at point 92. Total amounts during the 35.9 years from 1938 to 1974 are as high as 1794.6 ft. Erosion is the dominant process along this coast from points 92 to 95. At point 96 deposition has occurred. Between point 97 and Monomoy Point, deposition and the eastward migration of the shore continued from 1938 to 1971. Between 1971 and 1974 this shore eroded and migrated westward.

Several generalizations regarding areas of net recession or accretion along the coast were made, based on the data in Tables VI and VII. The high-water line along the coast from Long Point to mid-Provincetown Beach (points 1 to 6) moved landward except at point 4 where net accretion was dominant. Net accretion also predominated along the coast from Race Point to Pilgrim Spring State Park (points 9 to 24). Net erosion prevailed along most of the coast from

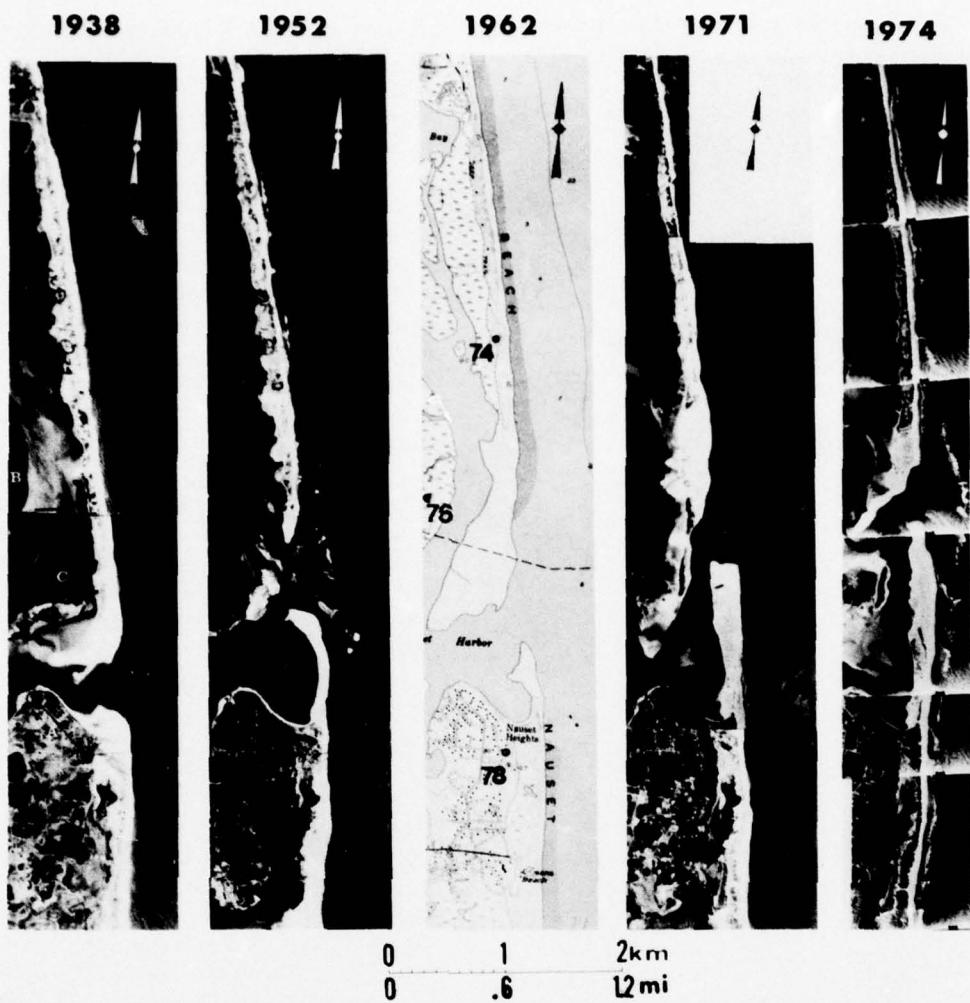

Figure 7. Shoreline changes along Nauset Beach, 1938-1974 (A — Nauset Heights, B — marshy islands, C — marshy island that periodically becomes part of the north spit).

Head of the Meadow Beach (point 31) to the southern portion of Monomoy Island (point 96). Minor net accretion occurred at points 37, 39, 49, 51, and 59. Net accretion prevailed near the southern tip of Monomoy Island at point 97.

The large variability in the high-water line data between the sampled years and along the shoreline (Fig. 4) suggests that the loci of erosion and accretion are continuously changing locations and intensity and are produced by very complex, mobile processes. Generally, the data showing the most variability are from 1971-1974 (3.2 yr), the shortest interval, while the data from 1938-1952 and 1952-1971 (13.6 yr and 19.1 yr, respectively) are less variable. The net change data (Fig. 5) are generally less variable than any of the incremental data. The high variability

from 1971-1974 may result from large, ephemeral changes that have not been countered by more typical conditions.

Goldsmith\* suggests that the littoral processes responsible for the complex variability of the shoreline changes may indicate the existence of several subcompartments, or that the migration of the sand waves or shoreline rhythms (Fig. 2 and 8) may have a major effect on the variable shoreline erosion/accretion. Komar (1976) gives a good summary of previous investigations on rhythmic topography and its relationship to shore processes and movement of erosion or accretion sites along the beach. Komar (1976) distinguishes two types of rhythmic topography, those associated with 1) cell circulation (rip currents) and 2) crescentic bars.

\* V. Goldsmith, personal communication, 1976.

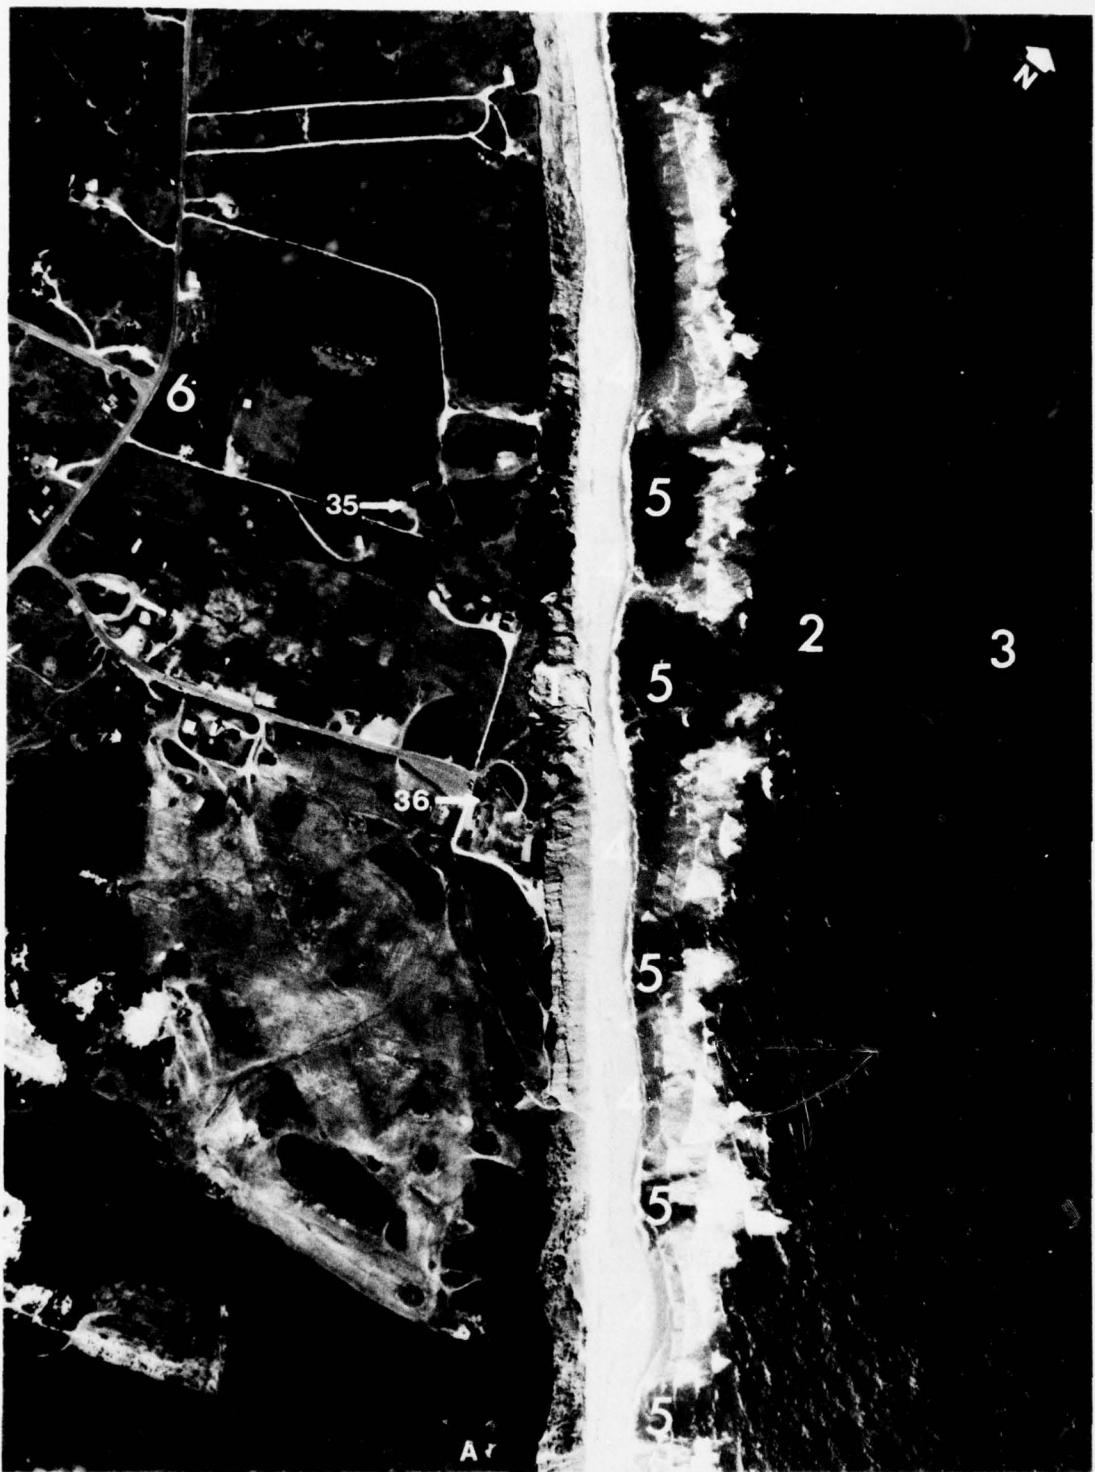

Figure 8. Sea cliffs (1) and sand waves (4) near Highlands area (6). Note high erosion embayment (5), turbid zone (2) possibly due partially to rip currents and sediment resuspension in the surf zone, and clear water (3) seaward.

Based on the studies of coasts in North Carolina, Vincent (1973) and Dolan et al. (1974) describe crescentic and rhythmic patterns 300 to 6000 ft in length (from crest to crest) as shoreline meanders. These meanders reveal information regarding the form of the inshore bar system and circulation patterns in the nearshore zone. Large meanders ( $> 2000$  ft), which usually form during storms parallel to rhythms of the outer bars, appear to be regions of erosion caused by wave convergence over long offshore shoals, and often occur singularly during storms. Smaller meanders ( $< 2000$  ft) usually follow rhythms of the inner bar and are indicative of the accretive, poststorm beach phase. They also report that local, inshore phenomena determine the presence and size of these features. Based on the classification of Dolan et al. (1974), the meanders on Cape Cod are "sand waves" (also called "giant cusps," "storm cusps," and "shoreline rhythms"). They occur as fields of echelon points and embayments (Fig. 8) with spacing that varies from 300 to 9000 ft (medium scale). Usually found where beach material is sand, the topographic association of sand waves is the beach berm-offshore bar and trough system; they are rhythmic and migrate in a downdrift (longshore) direction. Sand waves can persist for weeks to years, and they have various suggested formative processes that are associated with the dynamics of longshore transport, including wave action, and the formation of nearshore circulation cells (compartments), edge waves, and back eddies of longshore transport currents.

Dolan and Vincent (1973) report on the utility of aircraft photography in analyzing the relationships between sand waves and offshore bars. They conclude that remote sensing is the only method currently available for investigating the aerial and temporal distributions of crescentic coastal features. The seaward projections and landward embayments of the sand waves are subaerial manifestations of transverse bars and troughs. The presence of sand waves with their crescentic shapes, uniform sizes, and varying dynamics indicates that sandy coastlines respond to a system of interrelated processes, and that sand waves are not randomly distributed irregularities that depend on local conditions. Dolan and Vincent (1973) report that aerial photographs are ideal for providing the essential regional view of the complex systems that include sand waves, coastal processes, and offshore bar formations.

Goldsmith and Colonell (1970) performed detailed studies of the relationship between beach changes and wave energy along the shore of Monomoy Island. They described three distinct types of offshore bars and related their position to sites of shoreline erosion and accretion. They concluded that large variations in coastal erosion and accretion are related to the nonuniform distribution of wave energy arriving at a section of coastline. This nonuniformity, resulting from wave refraction around irregular offshore bathymetry, appears to produce sand waves flanked by erosional zones. According to Goldsmith and Colonell, wave refraction calculations show zones of alternately converging and diverging orthogonals. Zones of converging wave orthogonals (wave energy concentrations) correlate with locations of the beach where greatest amounts of erosion occur.

There is considerable debate regarding, and current research addressing, the relationship between sand waves and their formative processes or conditions. However, it is generally agreed that 1) sand waves are sites of accretion (projection) bordered by sites of erosion (embayments), 2) that they indicate a complex interplay between changing littoral processes, waves, and nearshore bedforms, and 3) that they migrate along the shore. A detailed ground investigation would be required to provide data addressing the complexity of this interplay. It is not the purpose of this report to investigate sand waves; however, their presence along the outer shore of Cape Cod is indicative of the complexity of the coastal processes active there. This complexity may be a partial explanation for the highly variable shoreline data presented in this report.

#### Shoreline changes: Cliff recession

The sea cliffs along this coast are variable in height and reach nearly 180 ft two miles north of Newcomb Hollow Beach. The cliffs are essentially continuous from Head of the Meadow Beach (point 31) to Nauset Beach (point 69), although gaps in the cliffs occur where stream valleys intersect. Measurements (Table V) were made from the reference points to the cliff break at the top and the cliff base (for example, a and c, respectively, in Fig. 2), and values for net change, rates of change, and total change were determined (Tables VIII and IX, Fig. 9, 10 and 11). The accuracy of the values near the northerly end of the cliffs and near gaps in the cliffs is suspect because it was extremely difficult to clearly determine the position of the cliff break

Table VIII. Total changes (ft) and the annual rates of change (ft/yr) in positions of the cliff break and cliff base.

and base in these areas. Figure 12 shows the irregularity of the cliff break (a) at Head of Meadow Beach. The irregularity of the break is also well illustrated in plate 2B of Zeigler et al. (1959). Figure 13 shows the variability of the cliff break (2), the dune area (1), and the cliff face (3) in this area. The cliff base (c in Fig. 2) is distinct along this portion of the coast.

Initially only distances from reference points to cliff breaks were measured. However, because it was frequently difficult to determine a true cliff break at several points, measurements were also made to the cliff base which was generally a more distinct feature. The plus (+) values in Tables VIII and IX indicate that the distance from a reference point to a break or base was greater than that in the previous year's photographs. This is possibly a result of inaccurate determination of the location of the true break or base. In several areas the location of the feature was not readily apparent due to overexposure on the photograph. In addition, plus values may indicate that slumping has occurred (note the area north of "A" in

†Net change/35.9 years.

\*\*Summation of total changes in Table VIII; - in this column indicates total changes from Table VIII were always erosional.

Fig. 2) and that the measured distances of the base or break were temporarily greater than those measured in the previous time period.

The incremental mean annual changes for the cliff base (Table VIII, Fig. 9) vary considerably but are generally less than 10 ft/yr. Net changes of the base location from 1938 to 1974 (Table IX) varied from 15.2 ft at point 42 to 262.2 ft at point 39. Net annual rates of change from 1938 to 1974 for the base varied from -7.3 ft/yr to +1.2 ft/yr (Fig. 10), for the break -3.4 ft/yr to +7.0 ft/yr. The greatest net changes occurred near Highland and north of Nauset. Zeigler et al. (1959) reported 20 ft of erosion from January to March 1956 and 30-50 ft of erosion at the Nauset parking lot in April 1958.

A least-squares regression was done to determine the degree of correlation between change in the location of the high water line and the distance from the approximate center of the cliffted portion of the shoreline (App. B). The correlation coefficients, from the entire coast are better for the longer intervals (1938-1952, 1952-1971, and 1938-1974), than for the 1971-1974 interval which had virtually no correlation. This suggests that the correlation may improve over a period of time longer than the 35.9 years of this survey. However, because of the complexity and variability of the coastal processes active along this shore, there may never be a good correlation.

Except for the 1971-1974 interval, the correlation coefficients were worse when using the data for the northern portion of the coast. With the southern data only, the coefficients improved when compared to the data for the entire coast, except for that from the 1971-1974 interval.

The regression coefficients show that there was no correlation between distance from the approximate center of the cliffted portion of the coast to the ends at Race Point and Monomoy Point. Although the cliffs are a primary source of sediment for the material in the littoral zone, there does not appear to be uniform movement of the material laterally along the shore.

#### Volumetric changes

As was mentioned previously, estimates of the net volume of sediment eroded or accreted along the coast from 1938-1974 (Table X) were based on the following empirical relationship:

1 ft of beach erosion perpendicular to the beach = 2 yd<sup>3</sup> of material/linear ft of beach.

Table X. Estimates of the net volume of sediment eroded or deposited from 1938 to 1974.

| Shoreline segments between reference points | Average net change (ft)* | Est net volume change per ft of beach ( $\text{yd}^3/\text{ft}$ ) | Distance along beach (ft) | Est net volume per segment of beach ( $\text{yd}^3$ ) |

†Nauset Beach.

\*\*Chatham Beach

††Monomoy Island.

Net changes in the position of the high-water line (Table VII) were used in making the estimates (Appendix B). These estimates reflected volumetric changes in the material eroded from or deposited on the foreshore area of the beach seaward of the mean high-water line. The material could have moved laterally along the shore, or simply could have shifted landward and seaward and not actually have been transported from a particular beach profile area. Areas of net average erosion or accretion were apparent. Net erosion occurred between points 1 to 9-10;\* 24-31 to 58-59; and 59-61 to 96-97. Net accretion occurred between 9-10 to 24-31, 58-59 to 59-61; and, 96-97 to 97. The estimated net volume of sediment eroded from 1938 to 1974 at the segment of beach points 1 and 9-10 was 5,253,500  $\text{yd}^3$ , and that deposited between points 9-10 and 24-31 was 7,251,380  $\text{yd}^3$ . The amount eroded between points 24-31 and 58-59 was 7,347,580  $\text{yd}^3$ , and that accreted between points 58-59 and 59-61 was 12,600  $\text{yd}^3$ . Erosion between points 59-61 and 96-97 amounted to 134,300,500  $\text{yd}^3$ , and accretion between points 96-97 and 97 was 196,560  $\text{yd}^3$ .

Comparisons of these estimated volumes were made to values derived from past field measurements. Zeigler and Tuttle (1961) and

Zeigler (1960) systematically surveyed four beaches (Highland, High Head, Race Point and New Beach) from 1953 to 1958. Volumetric changes during 1958 at the four beaches were as follows: 24.1  $\text{yd}^3/\text{linear ft}$  of beach at Highland Beach from January to June, 20.7  $\text{yd}^3/\text{linear ft}$  at High Head; 40.7  $\text{yd}^3/\text{linear ft}$  at Race Point from February to April, and 14.8  $\text{yd}^3/\text{linear ft}$  at New Beach from January to February. These short-term values are generally larger than the long-term estimates in Table X; however, Ziegler and Tuttle surveyed a larger portion of the beach (from the base of the cliffs or dunes to mean low water). This discrepancy may also be a result of using the conversion coefficient, 2  $\text{yd}^3/\text{linear ft}$  of beach. Volumetric estimates for this study were made for the beach between the position of the high-water line in 1938 and that in 1974. The horizontal length of measurement for this study was considerably shorter in most locations. In addition, Table X gives net volumes which average large and small changes for a 35.9-year period.

Zeigler et al. (1959) report maximum volumetric changes of 19.3  $\text{yd}^3/\text{linear ft}$  (cut) at Nauset during one storm tide and 13.7  $\text{yd}^3/\text{linear ft}$  (fill) at Highland during two storm tides. Average daily volumetric changes during storms

\*9-10 indicates midpoint along the shoreline between these two reference points.

from January to April 1958 varied as follows: a low of +0.03 and a high of +2.9 yd<sup>3</sup>/linear ft at New Beach, a low of +0.25 and high of +5.3 at Race Point, a low of -0.11 and high of +7.4 at High Head, and a low of +0.11 and high of +8.3 at Highland. Maximum cut and fill changes during one day from 1953 to 1958 were -3.9 and +5.4 at New Beach, -5.0 and +6.6 at Race Point, -9.5 and +5.7 at High Head, and -9.5 and +11.0 at Highland. These values were also calculated for the beach from the base of the cliffs or dunes to the mean low-water plane, and therefore should have been generally greater than those calculated for this study. In addition, estimates from this study show net changes over a 35.9-year period, and large short-term changes would be averaged within this number. The high variability of the erosional or depositional processes characteristic of this portion of the coast is also apparent for the more southerly coastline.

Goldsmith (1972) and Hayes (1972) reported that, between 1 November 1969 and 19 January 1970, a severe storm eastward of Hammonds Bend on Monomoy Island removed 19.8 yd<sup>3</sup>/linear ft of the beach and the berm retreated 50 ft. Data from other profiles on Nauset Spit and Monomoy Island acquired from 1968 to 1971 showed extremely high variability. Data from a profile approximately 3 miles north of the southern tip of Nauset Spit showed volumetric changes of 35.2 yd<sup>3</sup>/linear ft of sand eroded from 4 December 1969 to 3 January 1970.

#### Nodal zone location and direction of littoral transport

The location of the nodal zone along the outer coast which separates the net northerly littoral currents from the southerly is not well established (Fisher 1972). According to the U.S. Army Coastal Engineering Research Center (1975):

Nodal zones are usually defined by long-term average transport directions, but because of insufficient data, the location of the mid-point of nodal zones may be uncertain by up to tens of miles. In addition, short-term nodal zones most probably shift along the coast with changes in wave climate.

Hartshorn et al. (1967) suggested that the nodal point is near the center of the outer Cape, and Schalk (1938) suggested, based on sediment data, that the shoreline opposite the mouth of the Pamet River is the nodal point. However, Fisher reported that the dominant waves ap-

proach the coast from the east-northeast (ENE) and that the nodal point may currently be located just south of Gull Pond in the area delineated by a tangent drawn perpendicularly to the ENE direction. Field data on median grain size along the shore from Provincetown to Chatham support this location (Fisher 1972). Approximately 6.5 miles of coast between Spectacle Pond and North Truro Air Force Station is perpendicular to the ENE dominant wave direction as shown on the LANDSAT imagery. The sea cliffs within this zone vary in height from 177 ft northeast of Featherbed Swamp to less than 50 ft in several locations (USGS 7.5-minute topographic maps).

All available LANDSAT-1 and -2 imagery acquired from 1 September 1972 to 28 May 1975 and the aerial photographs from these four years were inspected for evidence of littoral transport patterns, which may be used to infer the nodal zone location. Generally, transport patterns were not visible, although the patterns of coastal features and nearshore bathymetry were used to deduce the area within which the nodal point may migrate during varying meteorological and seasonal conditions.

LANDSAT-1 image 1274-14562 was acquired on 23 April 1973 during lower low water (Table XI). A band 4 frame (Fig. 14) of this image shows

**Table XI. Predicted tides on days when usable LANDSAT imagery was available (from NOAA Tide Tables for the East Coast of North and South America).**

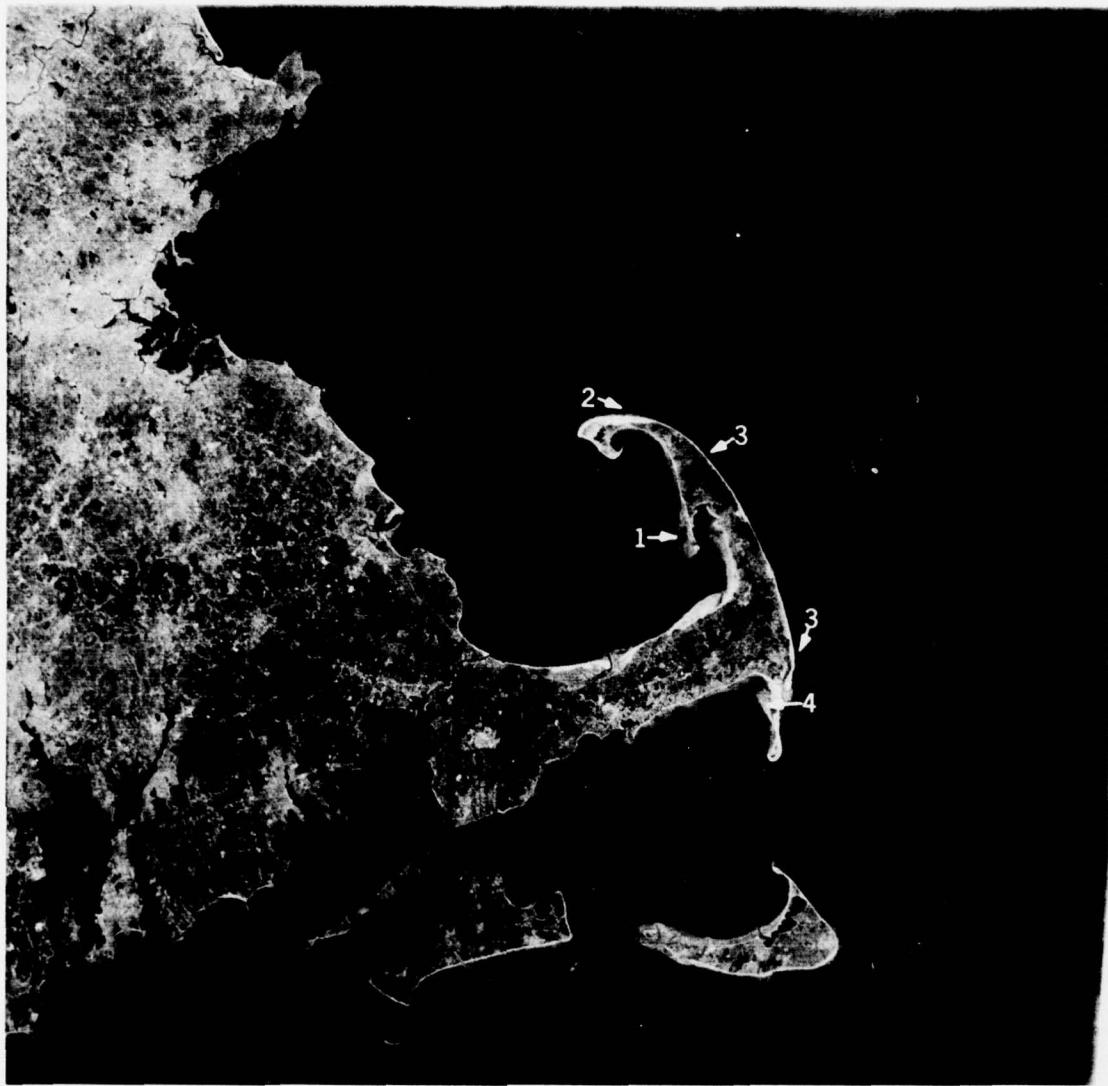

Figure 14. Cape Cod, 23 April 1973; LANDSAT-1 MSS band 4 image 1274-14562 (ground coverage is 100 miles  $\times$  100 miles).

several coastal shoals that were verified on the National Ocean Survey Nautical Chart 1208: Peaked Hill Bar (2) located north of the Provinceland Hook, Billingsgate Shoal (1) southwest of Wellfleet, and unnamed shoals (4) west of Monomoy Island and south of Nauset Beach. Close inspection of the outer coast (3) shows an offshore bar extending as far south as Nauset Beach. A band 5 frame (Fig. 15) of the same scene shows numerous patterns which appear to be rip current plumes (1) extending as far as 1 mile offshore. The current plumes appear to move southeasterly several miles from shore. Many of the shoals (2) southeast of Monomoy

Point and within Nantucket Sound are evident. Internal wave nets (3) are also apparent approximately 20 miles east of Nantucket Island.

Band 4 image 1508-14530 (Fig. 16) was acquired during flood tide. Turbidity (1) in the surf zone appears greater than observed on the 23 April image. The patterns in the Nantucket area are also less evident or absent. Band 5 image 1598-14505 (Fig. 17) acquired during early flood tide shows wave patterns (1) reflected along the northern coast from High Head (2) to Race Point; littoral transport would be primarily from east to west in this area. The shoal (3) at the mouth of Nauset Harbor suggests that a southerly near-

Figure 15. Band 5 of same image as in Figure 14.

shore current predominates at this location. Band 5 image 1724-14472 (Fig. 18) acquired during early ebb tide shows several sets of internal wave nets (1) east of Cape Cod. These suggest that water masses of different densities are mixing in this area. However, no additional information about the coastal currents is observable on this image.

The following LANDSAT-1 and -2 images were reviewed but additional information was not obtained: 2036-14442 (27 February 1975), 2090-14441 (22 April 1975), 5012-14360 (1 May 1975) and 2126-14440 (28 May 1975). The LANDSAT imagery had limited use for this study. Surface suspended sediment concentrations in the

nearshore zone were generally too low for detection of circulation patterns.

The area that protrudes in the most north-easterly direction is the area near Highland Light and Beach; the area in the most easterly direction is Nauset Beach. Depending on the direction of weather fronts, the nodal point for littoral currents would generally shift either northward or southward within this zone. Goldsmith\* points out that the location of the "nodal point" would actually change depending on wave approach, i.e. several northeast storms in a row vs no storm conditions. The shape of the coast from Highland Light to Long Point suggests that the net littoral transport directions are westerly

\* V. Goldsmith, personal communication, 1976.

Figure 16. Cape Cod, 13 December 1973; LANDSAT-1 MSS band 4 image 1508-14530.

to Race Point, then southeasterly and finally northeasterly to Long Point. South of the nodal zone, the shapes of Nauset Spit and Monomoy Point indicate that net littoral transport is southward. Fisher (1972) reports that erosion of the sea cliffs provides much of the sediment for deposition northwest and south of the clifftop portion of the coast. Goldsmith\* believes that it is an oversimplification to say that sand being eroded from the center cliffs is moved to both flanks. The large local variability in shoreline changes suggests that the littoral processes are far more complex.

#### Error evaluation

There are several sources of error in measuring the distance from selected reference points to beach features as observed on aerial photographs or satellite imagery. Strong onshore winds can cause higher-than-normal water levels, producing distances that are lower than the true value. In addition, if imagery is acquired during spring or neap tide, the high-water line would be higher or lower than normal. Variations in beach slope could also produce significant differences in the location of the high-water line. Therefore, poststorm imagery could show atypical conditions.

Figure 17. Cape Cod, 13 March 1974; LANDSAT-1 MSS band 5 image 1598-14505.

The amount of detail about the cliff break and base was variable. In 1938 and 1952, some of the photographs were overexposed. This caused several sections of the coast to appear white and the shoreline features to be virtually indistinguishable. It is also possible that the points on the cliff break and base were not located accurately. Slumping along the cliffs could cause the break to be indistinct and the base to appear to be temporarily more seaward than if the slumping had not occurred.

In addition to these potential sources of error caused by natural phenomena, errors probably

resulted from the analytical procedures used. Measuring angles drawn by the photointerpreter may not have been exactly the same, and this might have introduced variability in the data. The Vernac instrument was used throughout the study to minimize variability due to equipment, and errors due to scale changes within each photograph were minimized by determining the average scale nearest the stable reference points in the central portion of the photograph. In spite of these efforts, however, it is likely that scale variations were the main source of measurement error.

Figure 18. Cape Cod, 17 July 1974; LANDSAT-1 MSS band 5 image 1724-14472.

## SUMMARY AND CONCLUSIONS

The large range in the measured values for changes in positions of the high-water line and the cliffs illustrates the highly mobile nature of this coastline. A major cause of this mobility is the erodable character of the glacial material on Cape Cod. Because the photographs used for this study showed conditions at a given time, many of the rapid, temporal changes were not documented. The aerial photographs were useful in determining the amount of net change that results from these many ephemeral changes.

Aerial photographs acquired in 1938, 1952, 1971, and 1974 were used to measure changes in positions of the high-water line and the cliff break and base. Maps illustrating the water line changes were prepared for each year's photographs. The greatest net changes in positions of the high-water line from 1938 to 1974 occurred in the northern (points 1-36) and southern (points 65-97) portions of the coastline. Net changes in the north varied from -10.2 ft (point 12) to +321.4 ft (point 13) and in the south from -65.4 ft (point 65) to -1794.6 ft (point 92). The central coast (points 37-61) was generally more stable with net changes varying from -6.8 ft

(point 42) to -157.6 ft (point 43). Values for net changes in positions of the cliff break and base were also variable. The cliff-break position varied as little as +9.8 (point 39) to as much as +251.0 ft (point 40) for the period 1938 to 1974. Variability in the cliff base was high: +2.0 ft (point 32) to -262.2 ft (point 39). The net annual rates of change for the positions of the water line and the cliff features compared favorably with data acquired from ground surveys.

Volumetric changes calculated were generally lower than those determined from survey data. However, the latter data were acquired more frequently and the effects of severe storms were included. The calculated values from this study show longer term changes, and therefore the more dramatic short-term values over the entire period from 1938 to 1974 are averaged into the long-term patterns of change. Generally, LANDSAT imagery was not useful in evaluation of littoral transport, although the coastal features observed on the imagery could be used to infer directions of littoral currents and the nodal point location.

Errors in measurement were probably due to analytical procedures, photo-scale variations, and inability to accurately identify and locate beach features because of cliff slumping or overexposure on several photographs. In spite of these potential errors, the values determined are valid as reconnaissance data for the more detailed surveys that should follow.

## FUTURE RESEARCH

Based on the results of this investigation, the following research topics are considered worthwhile pursuing.

1. Analysis of coastal currents during normal weather and poststorm conditions could be accomplished utilizing dye as a tracer and low altitude aircraft photographs. This would provide data for accurate delineation of the dominant directions of littoral currents and the location of the nodal point.

2. The nature of the rapid and temporal (generally the larger-scale) changes in coastal configurations, landforms, and backshore features could be determined from aerial photographs acquired after storms. Restoration to prestorm conditions would vary along the coast and indicate where normal processes are most active. Estimates of material transported during storms could also be made from poststorm photographs.

3. The water-penetrating capability of various photographic film/filter combinations could be used to study changes in nearshore bathymetry. These data would be useful in estimating longshore transport of material during normal and storm conditions, different wind regimes, and various seasonal and tidal conditions.

## APPENDIX B: SUPPLEMENTARY DATA FOR ESTIMATING SHORELINE CHANGE

**Table B1. Calculations for estimating the average net change (ft) along a shoreline segment.**

| <i>Shoreline segment endpoints</i> | <i>Calculations for determining net change between points*</i> | <i>Average net change for a shoreline segment</i>   |
|------------------------------------|--|---|
| 1 to 3-4                           | $3-4 = \frac{(-179.3) + (+69.0)}{2} = -55.15$                  | $\frac{(-252) + (-179.3) + (-55.15)}{3} = -162.15$  |
| 3-4 to 4-5                         | $4-5 = \frac{(+69) + (-119.6)}{2} = -25.3$                     | $\frac{(-55.15) + (+69) + (-25.3)}{3} = -3.81$  |
| 4-5 to 9-10                        | $9-10 = \frac{(-118.7) + (+124.5)}{2} = +2.9$                  | $\frac{(-25.3) + (+119.6) + (-14.7) + (118.7) + (+2.9)}{5} = -55.08$  |
| 9-10 to 10-12                      | $10-12 = \frac{(+124.5) + (-10.2)}{2} = +57.15$                | $\frac{(+2.9) + (+124.5) + (57.15)}{3} = +61.51$  |
| 10-12 to 12-13                     | $12-13 = \frac{(+321.4) + (-10.2)}{2} = +155.6$                | $\frac{(+57.15) + (-10.2) + (+155.6)}{3} = +67.51$  |
| 12-13 to 18-20                     | $18-20 = \frac{(+102.9) + (-39.4)}{2} = +31.75$                | $\frac{(+155.6) + (+321.4) + (+223.6) + (+102.9) + (+31.75)}{5} = +167.05$                                    |
| 18-20 to 20-24                     | $20-24 = \frac{(+97.4) + (-39.4)}{2} = +29$                    | $\frac{(+31.75) + (-39.4) + (+29)}{3} = +7.11$  |
| 20-24 to 24-31                     | $24-31 = \frac{(-316.5) + (+97.4)}{2} = -109.55$               | $\frac{(+29) + (+97.4) + (-109.55)}{3} = +5.61$   |
| 24-31 to 36-37                     | $36-37 = \frac{(-130.2) + (+12.2)}{2} = -59$                   | $\frac{(-109.55) + (-316.5) + (-313.2) + (-195.3) + (-189.1) + (-103.9) + (-130.2) + (-59.0)}{8} = -177.09$   |
| 36-37 to 39-40                     | $39-40 = \frac{(-73.3) + (+39.4)}{2} = -16.95$                 | $\frac{(-59) + (+12.2) + (+39.4) + (-16.95)}{4} = -6.08$  |
| 39-40 to 44-49                     | $44-49 = \frac{(-116.0) + (+28.7)}{2} = -43.65$                | $\frac{(-16.95) + (-73.3) + (-29.9) + (-6.8) + (-157.6) + (-116.0) + (-43.65)}{7} = -63.45$                   |
| 44-49 to 49-50                     | $49-50 = \frac{(-94.7) + (+28.7)}{2} = -33$                    | $\frac{(-43.65) + (+28.7) + (-33)}{3} = -15.98$   |
| 49-50 to 50-51                     | $50-51 = \frac{(-94.7) + (24.4)}{2} = -35.15$                  | $\frac{(-33) + (-94.7) + (-35.15)}{3} = -54.28$   |
| 50-51 to 51-58                     | $51-58 = \frac{(+24.4) + (-20.3)}{2} = +2.05$                  | $\frac{(-35.15) + (+24.4) + (+2.05)}{3} = -2.9$   |
| 51-58 to 58-59                     | $58-59 = \frac{(-20.3) + (+16.3)}{2} = -2.0$                   | $\frac{(+2.05) + (-20.3) + (-2.0)}{3} = -6.75$  |
| 58-59 to 59-61                     | $59-61 = \frac{(-24.2) + (+16.3)}{2} = -3.95$                  | $\frac{(-2.0) + (+16.3) + (-3.95)}{3} = +3.45$  |
| 59-61 to 65-67                     | $65-67 = \frac{(-65.4) + (-135.7)}{2} = -100.55$               | $\frac{(-3.95) + (-24.2) + (-65.4) + (-100.55)}{4} = -48.52$  |
